Abstract

We demonstrate that an economical two Higgs doublet model can explain the electron and positron excesses in the recent ATIC and PAMELA experiments by the three body decays of the dark matter (DM) fermions without requiring the fine turning of the couplings and degeneracy of masses. We also show that the mass and lifetime of the decaying DM particle may not be fixed to be around 1 TeV and 10^{26} sec, respectively. Moreover, we note that this model includes a stable dark matter candidate as well.

The observed neutrino oscillations [1] and evidence for dark matter (DM) [1] imply physics beyond the standard model. In addition, recently reported PAMELA [2]/ATIC [3] cosmic-ray measurements show the positron/electron excess above the calculated background for the energy of order 100 GeV. These data is consistent with the previous measurements of the high energy electrons and positrons fluxes in the cosmic ray spectrum by PPB-BETS [4], HEAT [5] and AMS [6]. The, so-called, PAMELA/ATIC (P/A) anomaly can be explained by either annihilations or rare decays of DM particles. However, the possibility of the DM annihilations requires a boost factor of order $10^2 - 10^3$ to make it consistent with the thermally averaged annihilation cross section obtained from the observed relic density, whereas the analysis of the DM distribution indicates that the most probable boost factor should be of order 10 [7, 8]. On the other hand, the long enough lifetime of the decaying DM is achieved by using either some arbitrary small couplings (see Refs. [8, 9, 10, 11] and references therein) or large scale suppressions associated with high-dimensional operators at the low energy in the contexts of supersymmetry [12], technicolor [13], hidden gauge boson [14] and hidden fermion [15] models. In particular, DM decays through three-body channels have been discussed in Refs. [12, 15]. In this letter, we would like to explain the P/A result by three-body decays of DM fermions in a simple extended two-Higgs doublet model.

We introduce two neutral leptons N_k with the masses M_k ($k = 1, 2$) and second doublet scalar η with the mass M_η in addition to the SM particles. We assume that new particles are odd under a Z_2 symmetry. Note that the same particle content can be used to explain the small neutrino masses with either stable DM [16] or leptogenesis [17]. The new Majorana mass term and Yukawa couplings can be written as

$$M_k N_k N_k + y_{ik} \bar{L}_i \eta N_k + \text{H.c.}, \quad (1)$$

where L is the lepton doublet and i and k are the flavor indexes. We consider the masses of $M_1 < M_2 < M_\eta$. Hence, N_1 is stable and N_2 can only decay to three, as shown in Fig. 1, or more particles.

The lifetime of N_2 is given by

$$\tau_{N_2} \simeq \frac{1}{\Gamma(N_2 \rightarrow N_1 \ell_i^\pm \ell_j^\mp)} = \frac{128(2\pi)^3}{3} \frac{M^4 M_2^3}{(M_{21}^2)^4}, \quad (2)$$

where $M_{21}^2 = M_2^2 - M_1^2$ is the DM leptons mass splitting and $M \equiv M_\eta/y$ with $y \equiv |y_{ik}|$. The energy distribution of electrons/positrons produced in a single three body decay of N_2

FIG. 1: Diagram for the DM decay.

can be written as

$$\frac{dN_e}{dE} = \frac{72M_2^3}{(M_{21}^2)^4} \left(M_{21}^2 - \frac{16}{9}M_2E \right) E^2. \quad (3)$$

We use the same method to calculate the electron/positron flux as that in Refs. [18, 19, 20]. The DM component of the primary electron/positron flux is given by

$$\Phi_e^{DM}(E) = \frac{c}{4\pi M_2 \tau_{N_2}} \int_0^{M_{21}^2/(2M_2)} dE' G(E, E') \frac{dN_e}{dE'}, \quad (4)$$

where E is in units of GeV and c is the speed of light. All the information about astrophysics is encoded in the Green function $G(E, E')$, approximately given by

$$G(E, E') \simeq \frac{10^{16}}{E^2} \exp[a + b(E^{\delta-1} - E'^{\delta-1})] \theta(E' - E) \quad [\text{cm}^{-3}\text{s}]. \quad (5)$$

The coefficients of a and b [9] for the spherically symmetric Navarro, Frenk and White (NFW) density profile of the DM in our Galaxy [21] and the diffusion parameter δ are listed in Table I for the three propagation models of M1, MED and M2 [22], respectively, which are consistent with the observed Boron-to-Carbon ratio [23]. Here, we have neglected the charge-sign dependent solar modulation [24] and other astrophysical uncertainties [22], which could be significant at the energies below 10 GeV.

TABLE I: Coefficients of the approximate positron Green function of the NFW halo profile and the diffusion parameter δ for the propagation models of M1, MED and M2, respectively.

Model	δ	a	b
M1	0.46	-0.9809	-1.1456
MED	0.70	-1.0203	-1.4493
M2	0.55	-0.9716	-10.012

The total electron and positron fluxes are

$$\Phi_{e^-} = \xi \Phi_{e^-}^{prim} + \Phi_{e^-}^{DM} + \Phi_{e^-}^{sec} \quad (6)$$

and

$$\Phi_{e^+} = \Phi_{e^+}^{DM} + \Phi_{e^+}^{sec}, \quad (7)$$

respectively, where $\Phi_{e^-}^{prim}$ is a primary astrophysical component, presumably originated from supernova remnants, $\Phi_{e^{-(+)}}^{DM}$ is an exotic primary component from DM decays, $\Phi_{e^{-(+)}}^{sec}$ is a secondary component from the spallation of cosmic rays on the interstellar medium, and ξ is a free parameter about 1 to fit the data when no DM primary source exists. We take $\xi = 0.7$ to insure the flux calculation to be consistent with the ATIC data. For the background fluxes, we will use the parametrizations obtained in Refs. [24, 25], given by

$$\Phi_{e^-}^{prim}(E) = \frac{0.16E^{-1.1}}{1 + 11E^{0.9} + 3.2E^{2.15}} \quad [\text{GeV}^{-1}\text{cm}^{-2}\text{s}^{-1}\text{sr}^{-1}], \quad (8)$$

$$\Phi_{e^-}^{sec}(E) = \frac{0.7E^{0.7}}{1 + 110E^{1.5} + 600E^{2.9} + 580E^{4.2}} \quad [\text{GeV}^{-1}\text{cm}^{-2}\text{s}^{-1}\text{sr}^{-1}], \quad (9)$$

$$\Phi_{e^+}^{sec}(E) = \frac{4.5E^{0.7}}{1 + 650E^{2.3} + 1500E^{4.2}} \quad [\text{GeV}^{-1}\text{cm}^{-2}\text{s}^{-1}\text{sr}^{-1}], \quad (10)$$

where E is in units of GeV. In Fig. 2, we show the electron energy spectra (left) and the

FIG. 2: Electron energy spectra (left) and positron fractions (right) of the DM decays, where $M_1 = 10$ GeV, $M_2 = 1.5$ TeV, $\tau_2 \sim 10^{26}$ s, short-dashed, dot-dashed and long-dashed lines represent $M = 2.5 \times 10^{15}$, 3×10^{15} and 3.5×10^{15} GeV, small-black and large-gray dots stand for the observations of ATIC and PPB-BETS (left) and PAMELA and HEAT (right), and solid lines correspond to the backgrounds calculated from Eqs. (8)-(10), respectively.

FIG. 3: Legend is the same as Fig. 2 but $M = 3 \times 10^{15}$ GeV, $M_2 = 2$ TeV and short-dashed, dot-dashed and long-dashed lines represent $M_1 = 1, 1.1$ TeV and 1.2 TeV, respectively.

FIG. 4: Electron energy spectra (left) and positron fractions (right) for the decays of DM particles with $M_2 = 100$ TeV, $\tau_2 = 10^{24}$ s and $M_1 = (100 - 0.8)$ TeV (dashed lines) where small-black and large-gray dots stand for the observations of ATIC and PPB-BETS (left) and PAMELA and HEAT (right), and solid, short-dashed, dot-dashed and long-dashed lines correspond to the backgrounds, M1, MED and M2, respectively.

positron fractions (right) of $N_2 \rightarrow N_1 \ell_i^\pm \ell_j^\mp$ decays for $M_1 = 10$ GeV, $M_2 = 1.5$ TeV and $M = 2.5 \times 10^{15}$ GeV (short-dashed line), 3×10^{15} GeV (dot-dashed line) and 3.5×10^{15} GeV (long-dashed line), while Fig. 3 for $M = 3 \times 10^{15}$ GeV, $M_2 = 2$ TeV and $M_1 = 1$ TeV (short-dashed line), 1.1 TeV (dot-dashed line) and 1.2 TeV (long-dashed line), respectively. Here, the MED propagation model has been used and the background is represented by solid lines. In the above cases, the lifetime of N_2 is of order 10^{26} s, while the values of M can be achieved by taking $y_{ik} \sim 10^{-3}$ and $M_\eta \sim 10^{12}$ GeV. As seen from Figs. 2 and 3, the electron energy spectrum is more sensitive to the parameters in the model in contrast the positron

fraction. The P/A anomaly can be explained by the decays of N_2 with the mass higher than 1.5 TeV. We remark that for a lighter DM particle, the drop in the electron flux occurs at a lower energy compared to the ATIC data. In this sense, our mechanism is complementary to the annihilations of the DM fermions with masses below 1 TeV, shown in Refs. [26, 27]. Our model has more freedom in DM masses and lifetimes than the models with dominated two-body decays of DM particles since the drop in the electron flux in our case is determined by $M_{21}^2/(2M_2)$ rather than (DM mass)/2, see Refs. [8, 9, 10, 11] and references therein. Hence, the DM lifetime should be only higher than the age of the universe (4.3×10^{17} s). However, for higher M_i , a mass degeneracy is needed. For example, to have $\tau_2 = 10^{24}$ s, we need $M_2 = 10^5$ GeV and $M_1 = (10^5 - 800)$ GeV. The corresponding electron energy spectra and positron fractions are shown in Fig. 4 for the three propagation models of M1, MED and M2, respectively. We note that at the energies higher 400 GeV the signals are not sensitive to the propagation models. Production mechanisms of the DM leptons in the early universe and the upper bounds on their masses from the γ -rays observations will be considered elsewhere [29].

Finally, we remark that future collider bounds on the masses of heavy neutrinos [28] are not applicable in this Letter due to the Z_2 symmetry. However, our model can be verified by precise measurements of the electron spectrum and positron fraction, since the shapes of the corresponding curves are not very flexible. In particular, future measurements of the positron fraction at energies higher than 100 GeV can be crucial in testing the same origin of the ATIC and PAMELA electron and positron excesses.

In conclusion, we have investigated a new mechanism to generate the positron/electron excess from the decays of DM leptons. We have shown that the observed P/A anomaly can be explained by the three body decay of the neutral lepton N_2 with the mass $M_2 \gtrsim 1.5$ TeV and the lifetime $10^{17} \text{ s} \ll \tau_2 \lesssim 10^{26} \text{ s}$. One of the advantages of our mechanism is that there are no requirements for the degeneracy of masses and unnaturally small couplings or any other enhancement factors.
